ABSTRACT

Influence of solvation with various solvents is a vital issue for several applications of amino acids. Considering the impact of solvents and many other factors is an important point of research to get much more accurate data on their behavior. Hence, molecular modeling calculations were conducted for some amino acids in both cases; gaseous state and under the effect of several solvents; DMSO, acetonitrile, nitromethane, and methanol. DFT was utilized at B3LYP theoretical level and 6-31G(d,p) as a basis set. Geometrical parameters of both amino and carboxyl terminals were studied. Resulting data ascertain that various solvation processes impact the interested parameters that have to be considered for further applications.

Keywords: Amino acids; Histidine; Arginine; Solvation; DFT; Geometrical parameters.

1. INTRODUCTION

Livings composed of several macromolecules; carbohydrates, proteins, nucleic acids, and lipids. Proteins are treated as one of the most vital macromolecules where they carry out many vital processes. They may be found in the form of receptors, enzymes, signaling compounds, hormones, structural units of muscles and many other roles. Proteins are comprised of several polypeptide chains. Polypeptides have vital applications in our living bodies and in various scientific fields [1]. They contain hundreds of smaller entities called amino acids. Amino acids are the main structural and functional units of proteins. Twenty different amino acids present in all living organisms. They all share the same chemical structure where they all composed of a central alpha carbon atom linked to four entities; hydrogen atom, carboxyl group (C-terminal), amino group (N-terminal) and R-group, by single sigma covalent bonds. Twenty different alkyl groups yield 20 different amino acids. There are many aspects for classifying amino acids such as their chemical structure, their physical properties, chemical features, and nutritional requirements. Regarding the last aspect, they can be categorized into essential and nonessential amino acids. Methionine is one of the essential amino acids. It is one of the amino acids, besides cysteine, that has sulfur element in their R side-chain structure. Methionine (abbreviated as Met or M) has an amino group (which is protonated NH₃⁺ under biological conditions), carboxylic acid group (which is deprotonated COO⁻ under biological conditions), and an S-methyl thioether side chain. It is usually classified as an aliphatic nonpolar amino acid. It plays unique roles in protein structure and metabolism. Methionine is usually involved in growth control processes by indicating the start of the coding region and it is the first amino acid produced in a nascent polypeptide during mRNA translation. Methionine had been used in pharmaceuticals and biological applications for many decades and reported as effective corrosion inhibitors in different aggressive media for copper, aluminum, and others [2]. On the same manner, arginine is the same as methionine in being one of the essential amino acids [3]. It is usually converted in the body into nitric oxide directly by the aid of nitric oxide synthase enzyme. Arginine is a popular supplement for athletes as it is touted to increase nitric oxide activity in the body [4]. It is characterized by its high flexibility that can be attributed to its existence in the zwitter-ionic form, hence it contributes in the coordination with body salts through various interaction types such as hydrogen bonds and ionic bonds [5]. Therefore, arginine amino acid can undergo many conformational changes. Critical changes in metabolism processes of arginine that lead to a drop in its intracellular concentration [6, 7]. However, raising its levels in the body leads to induction of various global metabolic variations including a change from glycolysis to oxidative phosphorylation in activated T cells and stimulating the generation of central memory-like cells endowed with higher survival capacity in antitumor activity [8]. Activation of T cells consumes large amounts of glucose, fatty acids, and amino acids. Concentrations
of L-arginine in cells affect directly the metabolic fitness as well as the survival capacity of T cells that are crucial for anticancer response [9-11]. Unlike both methionine and arginine, tyrosine is one of the non-essential amino acids. It is usually found in several foods and drinks such as chicken, milk, cheese, almonds, peanuts, milk and many more. It is produced from dietary proteins such as salami and those that are aged, in particular, red wine and most types of cheese [12]. Tyrosine is one of the effective anti-depressant agents which, in addition, enhance the action of immune system in livings’ bodies [13]. It is one of the most frequently found amino acids in building up all types of proteins. Furthermore, it is common in improving memory, alertness, and learning specifically in stressful cases [14]. Tyrosine is the precursor amino acid for numerous neurotransmitters where it raises their blood level [15]. It is the It is usually utilized in sending chemical signals to the brain in several circumstances such as mental alertness. It is the precursor of dopamine neurotransmitter. Histidine amino acid was proven to be essential for all of the infants, normal adults and those suffering from uremia [16, 17]. It is one of the aromatic amino acids that is abundantly found in blood hemoglobin. Moreover, its nitrogen atom acts as an electron donor during the building processes of bonds including electron-poor atoms and it is also very important for plant growth and development [18]. Histidine, rather than other amino acids, play versatile roles in formulating structure and function of proteins [19-21]. This can be attributed to its unique side chain that composed of imidazole aromatic motif [22]. Conducting molecular modeling at various theoretical levels could be useful in understanding the chemical as well as structural features of amino acids and several structures and compounds as well [23-25]. Its concepts were greatly utilized in order to understand the interaction mechanism between chitosan and some amino acids [26]. Furthermore, they were conducted to investigate the impact of Hydrated Dioxin on both physical as well as geometrical parameters of amino acids [27]. These concepts were utilized also to study the influence of alkaline elements on the structural and electronic features of Glycine amino acid [28] and to investigate the interaction between aspartic acid and iron element [29]. In addition, it is also reported that calculations of molecular modeling always confirm the experimental data and introduce a reasonable way to understand important issues in all of the biological, chemical and environmental points of research [30-32]. Therefore and based upon the reported importance of molecular modeling, the present work is carried out to clarify the effect of solvation processes on the geometrical parameters of some amino acids using DFT level of theory.

2. MATERIALS AND METHODS
Calculation details.
Molecular models of some amino acids; methionine, arginine, tyrosine, and histidine, were built up and energy calculations were performed using GAUSSIAN 09 software which is implemented at Spectroscopy Department, National Research Centre (NRC) [33]. The calculations were conducted via Density Functional Theory (DFT) level at Becke-style 3-Parameter Density Functional Theory (using the Lee-Yang-Parr correlation functional) (B3LYP) [34-36] and 6-31g(d,p) as a basis set. Geometrical parameters of the built-up amino acids were studied in two states; gaseous state and under solvation with various solvents, for example, dimethylsulfoxide (DMSO), nitromethane (NM), acetonitrile (AN) and methanol (Meth).

3. RESULTS
3.1. Building up model molecules.
Four amino acids as well as other two aromatic ones, up as shown in figure 1. Two aliphatic amino acids, as well as the other two aromatic ones, were chosen for this study. They all possess the same chemical architecture with central alpha carbon atom linked to four moieties including hydrogen atom, carboxyl group (C-terminal), amino group (N-terminal) and alkyl group, by single covalent bonds.

![Figure 1. Model molecules of the four built-up amino acids (a) methionine, (b) arginine, (c) tyrosine, and (d) histidine.](image)

Methionine is the only built up molecule; that has a sulfur element, in its R group, which is surrounded by two methyl groups. Such sulfur atom enables methionine from making S-S bridges with other protein chains. Arginine is one of the basic amino acids since it contains three amine groups in its alkyl side chain. Such a structure enhances its positivity when placed in an alkaline media. Tyrosine is one of the aromatic amino acids where its side chain is composed of a terminal phenol structure that linked to the alpha central carbon atom through a methyl group. On the same manner, histidine has an aromatic structure. Its alkyl chain contains imidazole aromatic motif bonded to the alpha carbon by a methyl group via single covalent bond.

3.2. Energy calculations.
Energy calculations were conducted for the studied amino acids through DFT calculations using the B3LYP hybrid theoretical level and 6-31G(d,p) as our basis set. The calculations were carried out for the interesting amino acids in two cases; gaseous state and under solvation with various solvents, for example DMSO, nitromethane (NM), acetonitrile (AN) and methanol (Meth). Furthermore, geometrical parameters were studied in all cases. Table 1 illustrates the resulting geometrical parameters of the interested structures where both bond lengths and bond angles of C and N terminals of the investigated structures were...
Molecular modeling analyses for the effect of solvents on amino acids

Considered. Solvation of amino acids with various solvents seem to affect the geometrical parameters of their terminals, as illustrated in Table 1, which should be considered in further applications. For methionine amino acid, solvation with DMSO has no impact on the interested geometrical parameters except for the length of the C–O bond which is lowered from 1.4300 to 1.3013 Å, and the bond angle named HOC where it is increased from 109.4712° to 120.00°. However, both nitromethane and acetonitrile solvents have significant effect on all the studied parameters. Both of them cause the increment of the length of the two NH bonds as well as the OH one, and the OCO angle. It is obvious that the increment results from nitromethane are higher than that of acetonitrile. Similarly, both lower the other geometrical parameters where the length of both C=O and C–O bonds and the angles HNH and HOC are decreased. On the same manner of DMSO, methanol has no impact on the parameters of methionine except for HNH bond which is raised greatly from 109.4712° to 120.00°. Resulting data of tyrosine amino acid seem to be different from those of other amino acids where they all have the same effect on the studied parameters to nearly the same extent. They all cause the increasing of lengths of the two NH bonds, C=O and OH bonds, and the angles named HOC and OCO. However, they lead to the lowering of the CO bond length and HNH bond angle. Similarly, solvation of histidine with different amino acids has the same behavior, as previously explained for tyrosine, but with different ratios. Nitromethane has the greatest effect among the studied solvents in both cases of increment or decrement of interesting parameters. Both acetonitrile and methanol have typical effects on the studied parameters. Regarding arginine, it can be noticed that different solvents have various impacts on the studied parameters. They all have little effect on the two NH bonds. Furthermore, they have a greater decreasing impact on the HNH and HOC bond angles. However, they cause the increment of both C=O bond length and HOC bond angle. Methanol has the greatest effect with respect to other solvents. DMSO, acetonitrile, and methanol increase the C–O bond length, in contrary to nitromethane which decreases it. In addition, DMSO, nitromethane, and methanol lower the OH bond length, in contrast to acetonitrile that raises it from 0.9732 Å to 0.9780 Å.

Table 1. Geometrical parameters of C and N terminals of methionine (Met), tyrosine (Tyr), arginine (Arg) and histidine (His) amino acids in the gaseous state and under solvation with DMSO, nitromethane (NM), acetonitrile (AN) and methanol (Meth) solvents calculated at DFT using B3LYP/6-31G(d,p) level.

4. CONCLUSIONS

Molecular modeling calculations at DFT level were conducted for some interesting amino acids in two cases: gaseous state and under the influence of several solvation processes using diverse solvents; DMSO, AN, NM and Meth. DFT was carried out at the B3LYP theoretical level using 6-31G(d,p) basis set. Geometrical parameters of both amino and carboxyl terminals were studied. The conducted solvation processes ensure that solvation processes should be considered for future applications. Selecting a suitable solvent is an important point of research when starting a new investigation to eliminate the effect of solvents and get more accurate results. DFT proved to be a powerful tool to study amino acids which is in good agreement with the previous findings [37-43].
